Introduction

Multivariate analysis is useful when you have several different measurements on a set of n objects. In Genstat the measurements would usually be stored in separate variates, and these would have a unit for each object. The objects are often regarded as being a set of n points in p dimensions (p being the number of variates).

Many techniques, for example principal components analysis (Chapter 2) and canonical variates analysis (Chapter 3) are aimed at reducing the dimensionality. That is, they aim to find a smaller number of dimensions (usually 2 or 3) that exhibit most of the variation present in the data. This can help you determine patterns or structure in the data, as well as identify the relative importance of individual variables. Genstat has several menus for producing graphical representations, for example principal coordinates analysis (Chapter 4) and multidimensional scaling (Chapter 5). It also has facilities for modelling multivariate data, including multivariate analysis of variance (Chapter 8) and partial least squares.

Another important requirement is to take a set of units and classify them into groups based on their observed characteristics. Hierarchical cluster analysis (Chapter 6) starts with a set of groups each of which contains one of the units. These initial groups are successively merged into larger groups, according to their similarity, until there is just one group containing all the observations. Genstat also provide menus for nonhierarchical classification (Chapter 7), where the aim is to form a single grouping of the observations that optimizes some criterion such as the within-class dispersion, or the Mahalanobis squared distance between the groups, or the between-group sum of squares.

Chapter 9 describes the facilities for constructing classification trees, which allow you to predict the classification of unknown objects using multivariate observations. Regression trees, which predict the value of a response variate from multivariate observations are described in Chapter 10.

Finally, Chapter 11 describes how generalized Procrustes analysis can be used to obtain a consensus from assessors in activities such as wine tasting.

The book works through a series of straightforward examples, with frequent practicals to allow you to try the methods for yourself. The examples work mainly through the menus of Genstat *for Windows*, so there is no need for prior knowledge of the Genstat command language. Details of the commands for multivariate analysis can be found in Chapter 6 of the *Guide to the Genstat Command Language, Part 2, Statistics*.

1 Exploratory data analysis

Before you begin a multivariate analysis, it is sensible to investigate the properties of the data by looking at some plots and summary statistics.

We illustrate some of the insights that can be obtained by examining seven variables recorded in 41 towns in the USA, stored in the Spreadsheet file Pollution.gsh shown in Figure 1.1:

low	T Town	502	Temp	Manuf	Pop	Wind	Precip	Days	T Label
1	Phoenix	10	-70.3	213	582	6	7.05	36	Px
2	Little Rock	13	-61	91	132	8.2	48.52	100	Lr
3	San Francisco	12	-56.7	453	716	8.7	20.66	67	Sf
4	Denver	17	-51.9	454	515	9	12.95	86	Dv
5	Hartford	56	-49.1	412	158	9	43.37	127	Hf
6	Wilmington	36	-54	80	80	9	40.25	114	Wm
7	Washington	29	-57.3	434	757	9.3	38.89	111	Ws
8	Jacksonville	14	-68.4	136	529	8.8	54.47	116	Jv
9	Miami	10	-75.5	207	335	9	59.8	128	Mi
10	Atlanta	24	-61.5	368	497	9.1	48.34	115	At
11	Chicago	110	-50.6	3344	3369	10.4	34.44	122	Ch
12	Indianapolis	28	-52.3	361	746	9.7	38.74	121	In

Figure 1.3

First we open the Summary Statistics menu by clicking on the Summary Statistics suboption of the Summary Statistics option of the Stats menu on the menu bar (see Figure 1.4).

In the menu (Figure 1.5), we have entered all seven variates into the Variates box, selected the required summary statistics in the Options box, and checked the Histogram and Boxplot boxes in the Graphics box. The resulting output is shown below, and the plots are in Figures 1.6 - 1.19.

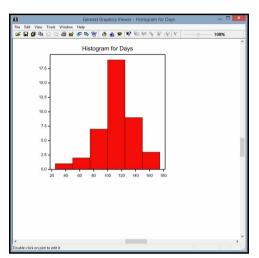

Figure 1.6

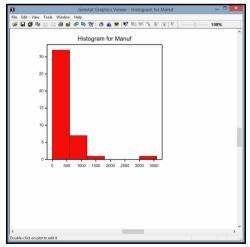

Figure 1.8

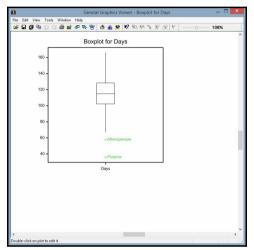

Figure 1.7

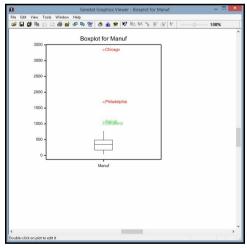

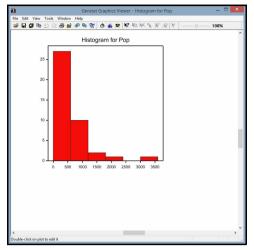

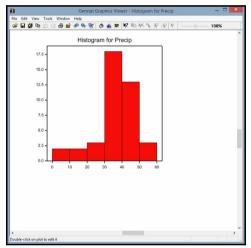

Figure 1.9

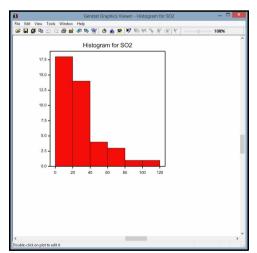

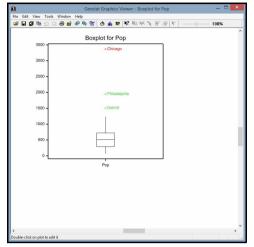

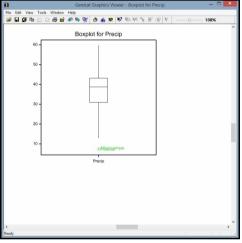

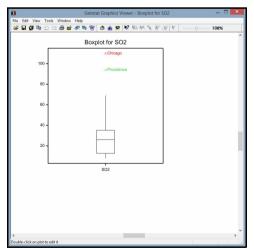

Figure 1.14

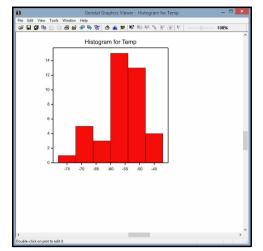

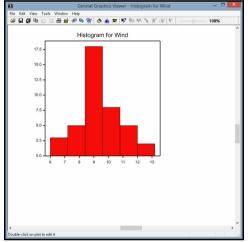

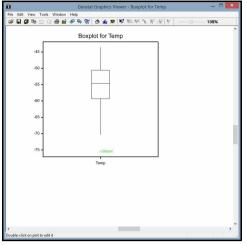

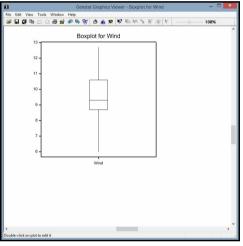

The main thing to notice in the plots and statistics show that the variables are on very different scales – and we will need to remember this in the later multivariate analyses.

To study the inter-relationships between the variates, we can select the Scatter Plot Matrix option of the Graphics menu on the menu bar. In the resulting menu (Figure 1.20), we just need to select the variates to plot and click on Run. The plot is useful for showing variates that are positively and negatively correlated, extreme observations and any clusters of the units.

The pollution data are plotted in Figure 1.21).

Figure 1.22

2 Principal components analysis

A major problem with multivariate data is that there are generally too many variates for you to be able to visualise the properties and inter-relationships of the data units easily. Principal components analysis (or PCP) provides one way to overcome this "curse of dimensionality". It aims to find linear combinations of the data variates that contain most of the variation between the units. The combinations (or *principal components*) indicate relationships between the variates, and also define planes in multi-dimensional space where the relationships between the units can be studied effectively. We shall illustrate this using the pollution data from Chapter 1.

The Principal Components Analysis menu (Figure 2.1) is obtained by clicking on the Principal Components line in the Multivariate Analysis section of the Stats menu on the menu bar. You first need to enter the data variates into the Data to be analysed window. Here we have chosen to enter all of the variates except SO2, which we will be treating as a response variate later in this Guide.

One important issue is to decide whether to base the analysis on sums of squares and products, or variances and covariances or

Available data:		Data to be	analysed:	
Days Manuf Pop Precip SO2 Temp Wind	~	Days Manuf Pop Precip SO2 Temp Wind		(
				4
Analysis based on Sums of square Variance-covari O Correlation matr	ance matrix		Rotate loading	S
Sums of square	ance matrix	Options	Rotate loading	S

Figure 2.1

correlations. The first two produce essentially the same analysis (there is just a common scaling of $\sqrt{(n-1)}$ applied to the variates, to convert from sums of squares to variances). The final setting, Correlation matrix standardizes each variate (by subtracting its mean and dividing by its standard deviation). This can be very useful if the variates do not share a common scale and show very different amounts of variation.

In the pollution data set, the variates are not only on different scales (see Chapter1), they are of inherently different types. So we have chosen to use the correlation matrix (which Genstat will calculate for us automatically, from the variates).

Clicking on the Options button produces the Principal Components Analysis Options menu (Figure 2.2), which controls the printed output from the analysis. We have set Display box to print Latent roots and Loadings, we have requested a scree plot, and we have set the Number of dimensions box to 6 which will give all the available latent roots and vectors. If you choose to

have less than the full number of dimensions, the Residuals check box can print residuals representing the information in the dimensions that have been excluded. The Number of dimensions setting also applies to results saved from the Principal Components Save Options menu, which is obtained by clicking on the Save button on the Principal Components Analysis menu.

The output is shown below.

Principal components analysis

Days Manuf Pop Precip Temp Wind	0.02196 0.70297 -0.69464 -0.06062 -0.13619 0.02453				

10

The first principal component defines the direction in which the towns exhibit the greatest variation. The second component defines the direction with the greatest variation of the directions orthogonal to the first component. The third component defines the direction with the greatest variation of the directions orthogonal to the first two components, and so on. Here, the first component contains about 37% of the variation, and the first and second components contain about 62%.

It is often interesting to interpret the directions. Those with mainly positive or mainly negative loadings represent "averages" while those with a mixture of signs represent "comparisons". Here, the first component is in the direction

0.23792 × Days + 0.61154 × Manuf + 0.57782 × Pop

- 0.04081 imes Precip + 0.32965 imes Temp + 0.35384 imes Wind

and seems to represent "quality of life". The second component is

```
0.23792 × Days + 0.61154 × Manuf + 0.57782 × Pop
```

- $0.04081 \times \text{Precip} + 0.32965 \times \text{Temp} + 0.35384 \times \text{Wind}$

and seems to be related to the wetness of the climate.

We have not printed the significance tests for equality of the final *K* roots as these cannot be used when the analysis is based on correlations. When the analysis is based on variances or on sums of squares, they can be useful for deciding how many roots are needed. Asymptotically (that is, as the number of units becomes large) these have chi-square distributions. However, this is not true for analyses based on correlations. To use the tests, we start by testing for equality of all the roots, then all except the first, all except the first and second, and so on, until the test is non-significant. The rationale is that, if we are to omit the final dimension, we should also omit all dimensions that are no more variable than that dimension.

An alternative, visual way of deciding how many roots are needed is to examine the scree plot. The plot for the pollution data, shown in Figure 2.3. shows the pattern that you would hope to find, with a clear jump up from the final roots (with low eigenvalues) to the earlier roots (with larger eigenvalues). This is more in line with the attitude that significance tests are not really relevant if you view principal components analysis mainly as a descriptive technique, where the aim is to find dimensions in which you can most effectively study the interrelationships of the data units.

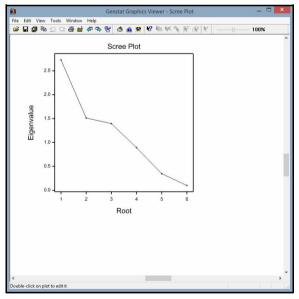

Figure 2.3

Here it seems that four principal components are needed. So, we change the number of dimensions in the Principal Components Analysis Options menu to four, check the box to plot the principal component scores, and select Label to label the points. Clicking on OK here, and then Run in the Principal Components Analysis menu, produces the plot in Figure 2.5.

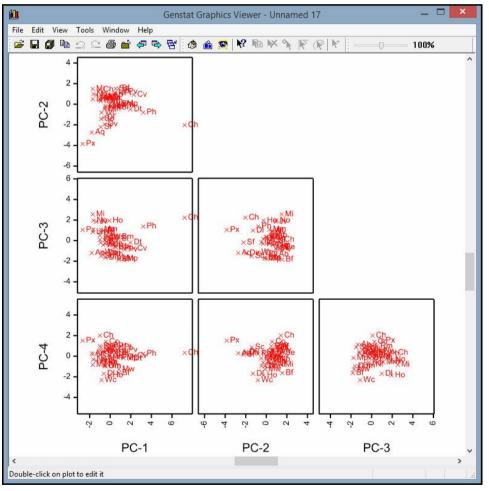

Figure 2.5

The menu uses the PCP directive, which is described in Section 6.2.1 of the *Guide to the Genstat Command Language, Part 2 Statistics*.

2.1 Principal-component biplot

Several of the multivariate analysis menus have a Biplot button, that becomes available once the analysis has been run. Biplots provide a convenient way of assessing the relationships between the individual observations in the analysis (here the towns), and their characteristics with respect to the variables in the data.

Clicking on the button in the Principal Components Analysis menu opens the menu in Figure 2.6, which has options to control the labelling of the plot, and the way in which the variables are represented. Here we

Available data:	Display in plot
Label Town	Convex hull
	Type of axes
	Predictive O Interpolative
	Multiplier for vector loadings:
	Labels for individuals (scores)
	O None O Unit labels O Numbers
	Labels: Label
	Labels for variables (biplot axes)
	○ None
	O Labels:
	Grouping factor:

enter the text vector Label to provide labels, and click on Run to produce the graph in Figure 2.7.

The display plots the individuals in the space defined by the first two dimensions of the multivariate analysis (from a PCP these will be the first two principal components). The plot also contains an "axis" for each variable (its *biplot* axis) that allows you to see how each individual's projection into this plane relates to its value for the variable concerned. Figure 2.7 shows the default, predictive axes. These show the values of the variables that are predicted by the projection into 2-dimensions that is defined for each point by the analysis; essentially this is done by taking an orthogonal projection of the point onto each the biplot axis. Genstat defines a *hot point* at the point for each individual. If you click on the hot point icon at the right-hand end of the Graphics Toolbar, and then click on one of the points, lines will be drawn from the point to the predictions. In Figure 2.7, we have done this for Phoenix, so you can see how this differs from the other towns. The lines can be removed again by clicking on the hot point a second time.

The angles between the biplot axes represent the correlations between the variables, and lines in opposite directions indicate negative correlation. So here we can see that temperature and wind have a strong negative correlation. The % variance of the principal components show the extent to which the plot summarizes the entire data set.

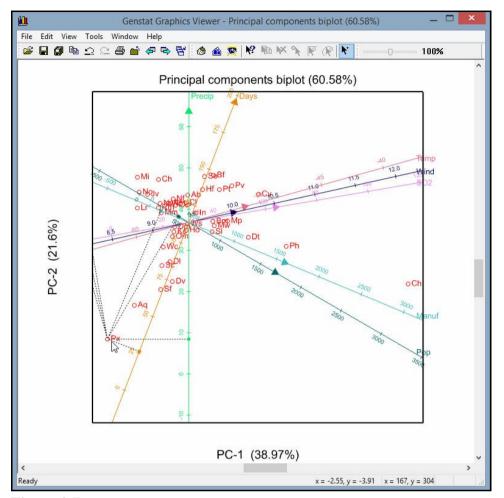

Figure 2.7

The alternative, interpolative axes show the values of the variables that would lead to a point being placed at the position of the selected point on the graph. So here the point is being predicted by the variables, rather than the variables by the point. This is done by taking the sum of a set of vectors, one in the direction of each variable, with lengths equal to the values of the variables for that point. To obtain interpolative axes, you should select the Interpolative button from the Type of axes radio buttons in the Biplot menu.

The Biplot menu uses the DBIPLOT procedure, which is described in Section 6.16.1 of the *Guide to the Genstat Command Language, Part 2 Statistics*.

2.2 Practical

Genstat spreadsheet file Exam.gsh (Figure 2.8) contains examination marks for 88 students in the subjects Mechanics, Vectors, Algebra, Analysis and Statistics. (See Practical 1.1 and Mardia, Kent and Bibby, 1979, *Multivariate Analysis*, Academic Press, London.)

Perform a principal components analysis. How would you interpret the directions in which the student marks exhibit the greatest variation? How important is Statistics in distinguishing the abilities of the students?

Row	Mechanics	Vectors	Algebra	Analysis	Statistics
1	77	82	67	67	81
2	63	78	80	70	81
3	75	73	71	66	81

12	55	67	59	62	44

Display a biplot from the analysis,

and use the hotpoints to see how the strongest and weakest students differ from the other students.

3 Canonical variates analysis

variates analysis Canonical is appropriate when the units are classified into groups. The aim is to find linear combinations of the data variates that represent most of the variation between the groups (rather than between the individual units, as in principal components analysis; Chapter 2). We illustrate the analysis using a classic data set, Fisher's Iris Data, which consists of measurements of sepal and petal lengths and widths on iris plants of three different species. This is available in Genstat spreadsheet Iris.gsh (Figure 3.1).

The Canonical Variates Analysis menu (Figure 3.2) is obtained by clicking on the Canonical Variates line in the Multivariate Analysis section of the Stats menu on the menu bar. You need to enter the data variates into the Data to be analysed window, and the factor defining the groups into the Grouping factor window. Clicking on the Options button produces the Canonical Variates Analysis Options menu, which controls the printed output from the analysis.

		Spreadshee	t [Iris.gsh]

Figure 3.2

In the Options menu (Figure 3.3), we have set the Display box to print Latent roots, Loadings, Canonical variate means and Distances. The Number of dimensions box is set to 2, which is the maximum possible here as there are only three species of iris in the data set. If you choose to have less than the full number of dimensions, the Residuals check box can print residuals representing the information in the dimensions that have been excluded. The Number of dimensions setting also applies to results saved from the Canonical Variates Save Options menu, which is obtained by clicking on the Save button on the Canonical Variates Analysis menu. The Graphics section of the menu is set to plot the data with the first canonical variate along the x-axis, and the second along the y-axis.

Adjustment terms

	1	2
1	-2.105	6.661

Inter-group distances

1 2	0.000 9.480	0.000		
3	13.393	4.147	0.000	
	1	2	3	

The results show that 99% of the between-group variation is in the direction of the first canonical variate:

 $0.829 \times \text{Sepal-Length} + 1.534 \times \text{Sepal-Width} - 2.201 \times \text{Petal-Length}$

 $-2.810 \times Petal-Width$

(using the coefficients in column 1 of the latent-vectors matrix). This is confirmed by the plot in Figure 3.4.

The matrix of canonical variate means presents the coordinates (or *scores*) for each group in the direction of each canonical variate. These are adjusted so that the centroid of the points, weighted by sizes of the groups, is at the origin. The adjustment term for each canonical original variates in order to achieve this. (See *Guide to the Genstat Command Language*, Part 2 Section 6.3.1 for more details.)

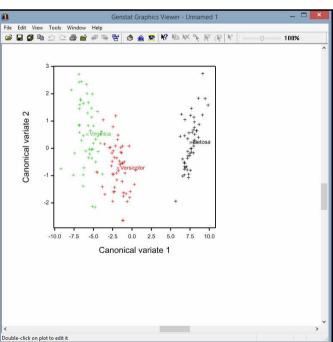

Figure 3.4

3.1 Practical

Genstat spreadsheet file Skull.gsh (Figure 3.5) contains data on 150 male Egyptian skulls from five different epochs (see pages 4 and 5 of Manly, 1986, *Multivariate Statistical Methods a Primer*, Chapman & Hall, London).

Perform a canonical variates analysis. Plot the first two canonical variates and study how the skulls differ between epochs.

w	Epoch	MaximumBreadth	BasibregmaticHeight	BasiolveolarLength	NasalHeight

4 Principal coordinates analysis

Principal coordinates analysis differs from principal components and canonical variates analysis in that the focus is more on the data units than the data variables. So the basic input is a symmetric matrix representing the "associations" between the data units. The menu (Figure 4.1) has radio buttons that you can use to specify how the the associations are supplied. Similarities are on a range from zero

Available data:	Association ma	atrix:	
	Analysis bas	ed on

Figure 4.1

(completely different) to one (absolutely identical). The alternative is to specify dissimilarities or distance which are zero when the two units are identical. Distances d are converted automatically to similarities s by the menu, using the transformation

 $s = -d^2$

(See the *Guide to the Genstat Command Language*, Part 2, Section 6.10 for more information.)

Figure 4.2

As an example, spreadsheet file Voting.gsh contains the number of times that 15 congressmen from New Jersey voted differently in 19 environmental bills (see Table 10.3 of Manly, 1986, *Multivariate Statistical Methods a Primer*, Chapman & Hall, London).

We shall analyse these as similarities, and so we first use the Calculations menu to convert the differences to proportions of times that they congressmen voted in the same way i.e.

(19-Diffvote)/19

(see Figure 4.3). We then enter the resulting symmetric matrix, Similarity, into the Association matrix box in Figure 4.1.

The Principal Coordinates Analysis Options menu (Figure 4.4) allows you to select the output to display, and specify the number of dimensions to fit. Here we have chosen to fit only two dimensions.

4 Principal coordinates analysis

In interpreting the plot (Figure 4.5), it is interesting to note that congressmen Daniels, Helstoki, Howard, Minish, Patten, Rodino, Roe and Thompson were Democrats, while congressmen Forsythe, Frelinghuysen, Hunt, Maraziti, Rinaldo, Sandman, Widnall were Republicans.

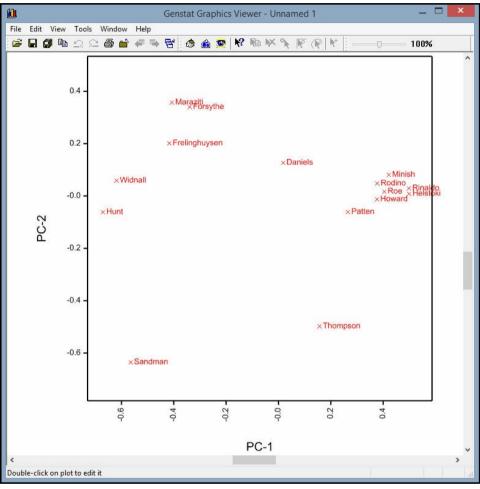

Figure 4.5

4.1 Practical

Genstat spreadsheet file Galaxy.gsh (Figure 4.6) contains distances between ten types of Galaxy. Use principal coordinates analysis to represent them in three dimensions.

Figure 4.6

5 Multidimensional scaling

Multidimensional scaling operates on a symmetric matrix which is assumed to represent distances between a set of units. It aims to construct coordinates of points, in a defined number of dimensions, whose distances are approximately the same as those in the original matrix. To illustrate the analysis we will try to recreate the locations of some British towns, based on figures for the shortest distances between each of them by road. The data are in the Genstat spreadsheet Roaddist.gsh (Figure 5.1). This is a symmetric matrix spreadsheet (as shown by the blanks above the diagonal).

The Multidimensional Scaling menu is obtained by clicking on the Multidimensional Scaling line in the Multivariate Analysis section of the Stats menu. In Figure 5.2, we have entered Distances as the distance matrix to use, and set the required number of dimensions to 3.

th an

Distance matrict

Method

Distances

Non-metric scaling (Monotone regression)

The algorithm starts with an initial configuration of points which it then modifies using a method

Multidimensional Scaling

Available data

known as *steepest descent*, until no further improvements are possible (see the *Guide to the Genstat Command Language*, Part 2 Section 6.12). To evaluate the configuration, it does a regression of the inter-point distances, calculated from the current configuration, against the supplied distances. The Method setting on the menu controls whether this is a "monotone regression" (which corresponds to what is known as *non-metric scaling*) or an ordinary linear regression (corresponding to *metric scaling*). It then compares the fitted

5 Multidimensional scaling

distances from the regression with the original distances using a quantity known as the *stress*.

The Scaling section of the Multidimensional Scaling Options menu (Figure 5.3) allows you to specify what to display from the analysis. Here we have asked to display the latent roots and the coordinates. It also controls whether the stress is calculated on a leastsquares scale, a least-squaressquared scale or a logarithmic scale. The Treatment of ties section of the options menu allows you to vary the way in which tied values in the supplied distances are treated. With the Primary setting, no restrictions

Display	Fitted distances	Treatment of ties Primary
Distances	Stress	O Secondary

Graphics		
Scatter plot matrix	of scores	
Display labels		<u>-</u>

are placed on the inter-point distances corresponding to tied distances. In the Secondary setting, the inter-point distances corresponding to tied distances are required to be as nearly equal as possible. The Tertiary setting is a compromise between the primary and secondary approaches to ties: the block of ties corresponding to the smallest distance are handled by the secondary method, and the remaining blocks of ties are handled by the primary method. This is particularly useful when the supplied distance matrix contains only a distinct values. Further information is given in the *Guide to the Genstat Command Language*, Part 2 Section 6.12, which describes the MDS directive that is used by these menus. The directive also has some additional facilities, for example the ability to try several automatically-generated initial configurations, or to supply your own.

If we click on OK here, and on Run in the Multidimensional Scaling menu itself, Genstat produces the output below.

Message: Default seed for random number generator used with value 33633

Multidimensional scaling

The Multidimensional Scaling Options menu has a check box to plot the coordinates (or scores) in a scatter-plot matrix showing all the pairs of dimensions. If you want to plot a single pair of dimensions, you first need to save the coordinates, using the Multidimensional Scaling Save Options menu (Figure 5.4) which is obtained by clicking on the Save button on the Multidimensional Scaling menu. Here we have asked to save the coordinates in a matrix called Locations, and to display these in a spreadsheet.

Save		
Coordinates	In:	Locations
Stress	In:	
Distances	ln;	
Fitted distances	ln:	
Display in spreadshee	t	

Figure 5.4

To plot the points, we need to convert the rectangular matrix spreadsheet of locations to a vector spreadsheet, by making this the active window and then selecting the Convert sub-option of the Sheet option of the Spread menu on the menu bar. In the resulting Convert Sheet menu (Figure 5.5), we change the radio button from Matrix to Vector, and click on OK to make the change. The columns will then be become variates, probably with names C1, C2 and C3, which can be used in the graphics menus in the usual way.

 Sheet type
 Matrix Name:

 Vector
 Locations 1

 Matrix
 Diagonal matrix

 Diagonal matrix
 Table

 Scalar
 K

×

Convert Sheet

We can then plot the points using the 2D Scatter Plot wizard in the usual way. First we use the initial Data menu (Figure 5.6) to select C1 for the ycoordinates, and C2 for the xcoordinates.

ata	Option	s Lines ar	nd Symbols	Key	X-Axis	Y-Axis	Frame

3											
			->								
	×										
-		2						D	un	Cancel	Defau

Then we select the Lines and Symbols tab of the Attributes menu (Figure 5.7), and arrange to label the points using the text Name. We also cancel the key on the Options tab.

Figure 5.8 shows the resulting plot of the first two dimensions, and Figure 5.9 shows a similar plot of the first dimension against the third dimension (showing some of the distortion in the data from a 2-dimensional solution).

6 Hierarchical cluster analysis

The hierarchical cluster analysis facilities in Genstat provide ways of grouping n objects into classes according to their similarity. It starts with a set of n clusters (or groups), each containing a single object. These initial clusters are successively merged into larger clusters, according to their similarity, until there is just one cluster (containing all the objects).

We shall use a set of data concerning mean mandible measurements of various types of modern and prehistoric dog (Higham, Kijngam & Manly, 1980, An analysis of prehistoric canid remains from Thailand, *Journal of Archaeological Science*, 7, 149-165). This data set is also discussed by Manly (1986, *Multivariate Statistical Methods a Primer*, Chapman & Hall, London). The data are in the Genstat spreadsheet Dog.gsh (Figure 6.1).

Spreadsheet [Dog.gsh]									
w	T type	mandible breadth	mandible height	first molar length	first molar breadth	first to third molar length	first to fourth premolar length		
1	Modern dog	9.7	21	19.4	7.7	32	36.		
2	Golden jackal	8.1	16.7	18.3	7	30.3	32.		
3	Indian wolf	13.5	27.3	26.8	10.6	41.9	48.		
4	Chinese wolf	11.5	24.3	24.5	9.3	40	44.		
5	Cuon	10.7	23.5	21.4	8.5	28.8	37.		
6	Dingo	9.6	22.6	21.1	8.3	34.4	43.		
7	Prehistoric dog	10.3	22.1	19.1	8.1	32.3	3		

Figure 6.1

The Hierarchical Cluster Analysis menu is obtained by clicking on the Hierarchical line in the Cluster Analysis subsection in the Multivariate Analysis section of the Stats menu on the menu bar. If you have already formed a similarity matrix, or a distance matrix or a dissimilarity matrix, you can enter its name straight into the Similarity matrix field in the menu (Figure 6.2). With a distance matrix, you would usually check the Use square root transform box.

Hierarchical Cluster Analysis Available data Data format Similarities O Dissimilarities / distances Use square root transform Similarity matrix dogmat Form similarity matrix Method Single link Run Options. 🔁 🗠 🗙 🕐 Defaults Cancel Bootstrap.

Figure 6.2

Alternatively, you can click on the Form Similarity Matrix button and use the Form Similarity Matrix menu (Figure 6.3). The names of the variates need to be entered into the Data values window, and you need to define a name (here dogmat) for the resulting symmetric matrix. You must also select the way in which the similarities are to be calculated from each variate.

vailable data:		Data values	Test
irst_molar_breadth irst_molar_length irst_to_fourth_premolar_lengt irst_to_third_molar_length nandible_headth nandible_height	h Default type of test: Euclidean V	first_molar_breadth first_molar_length first_to_fourth_premolar first_to_third_molar_length mandible_breadth mandible_height	euclidean euclidean euclidean
		<	2
Name of new matrix:	dogmat	Display	
Unit labels:	type	Similarity matrix	

Figure 6.3

Here we have chosen the default type to be "euclidean", which uses the geometric distance between the points representing each pair of objects. (A formal definition of this, and the other possibilities is in the *Guide to the Genstat Command Language*, Part 2, Section 6.1.2, where it describes the METHOD option of the FSIMILARITY directive, used by the menu.) You can change the types of individual data variables by double-clicking on their lines in the right-hand box. Finally, you can specify a vector (here the text called type from the first column of the spreadsheet) to label rows and columns of the matrix. When you click Run, the name of the matrix is automatically entered into the Similarity matrix field in the Hierarchical Cluster Analysis menu.

The Method field in the Hierarchical Cluster Analysis menu (Figure 6.2) contains a dropdown list box to specify the method of clustering to use. These differ according to the way in which they define the similarity between clusters containing more than one object:

,	5 6 5				
Single link	defines the similarity to be the maximum similarity between any pair of objects (taken one				
	from each cluster);				
Nearest neighbour	is a synonym for Single link;				
Complete link	defines the similarity between two clusters as the				
	minimum similarity between any pair of objects;				
Furthest neighbour	is a synonym for Complete link;				
Average link	defines the similarity, between a cluster and a new				
	cluster formed by merging two clusters, as the				
	average of the similarities with each of the original				
	clusters;				
Group average	is similar to Average link, except that the average is				
	over all the objects in the two merging clusters;				
Median sorting	if we regard the clusters as points in a				
	multidimensional space, when two clusters join				
	the new cluster is represented by the midpoint of				
	ine new craster is represented by the imapoint of				

the original cluster points.

Output from the analysis is controlled by the Hierarchical Cluster Analysis Options menu (Figure 6.4). For the dog example, we will simply print, and plot, the dendrogram. This displays the points at which the various clusters combine. allowing you to assess the relationships between the objects. If you specify a threshold in the Forming groups field of the options menu, Genstat will form a factor grouping all the objects that have been combined into a single cluster at that level of similarity. You can arrange to save the factor using the Hierarchical Cluster Analysis Save Options menu, obtained by clicking on the Save button in the Hierarchical Cluster Analysis menu (Figure 6.2).

Cuon	5)
Dingo	6)
Golden jackal	2)
Chinese wolf	4)
Indian wolf	3).

The dendrogram for the dogs, printed above and plotted (with better resolution) in Figure 6.5, shows that the modern and prehistoric dogs are most closely related, and that both of these are related to the Cuon and to the Dingo and Golden jackal. The Indian and Chinese wolves are related to each other more than any of the other dogs, but the similarity is not close.

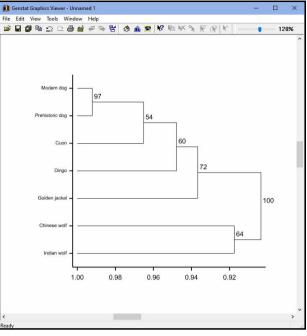

Bootstrapping provides a way to assess the reliability of the clustering. Does a cluster rely on just a few of the variables, or does it have wider support? Once you have run the cluster analysis, you can open the Bootstrap Hierarchical Cluster Analysis menu (Figure 6.6) by clicking the Bootstrap button in the Hierarchical Cluster Analysis menu. This takes a sample, with replacement, from the available variables. It forms a similarity matrix using the same settings as in the original analysis. It then does a cluster analysis, and records whether each of the original clusters is included.

Here we have left the default, which will form samples with the same number of variables as in the original analysis (6). We shall take 100 bootstrap samples, with seed zero meaning that Genstat will choose the seed for the random numbers automatically. As we have not used any random numbers earlier in this run, Genstat will initialise the random number generator from the system clock. Different seeds will give different results. So you should remember the seed (and enter it into the Randomization seed box), if you want to redo the bootstrapping and obtain same results in future.

The box for the Minimum similarity for forming clusters allows you to

Figure 6.7

ignore clusters that have low similarities. In our example, as all the clusters have a similarity greater than 0.9 (see Figure 6.5), it seems unnecessary to change this from the default of zero. We have chosen to print the clusters (with their replications over the samples), and to add these to the dendrogram, as shown in Figure 6.7. You can see that the cluster of modern dog with prehistoric dog occurs in almost all of the samples (97 out of 100), but the inclusion of Cuon has less support (only 54 samples).

Message: Default seed for random number generator used with value 955562

6.1 Practical

Genstat spreadsheet file Goblet.gsh (Figure 6.8) contains data on 25 goblets from prehistoric sites in Thailand (see page 147 of Manly, 1986, *Multivariate Statistical Methods a Primer*, Chapman & Hall, London). Perform a principal components analysis to study the relationships between the

StemHeight	UpperStemWidth	LowerStemWidth	OverallHeight	OverallWidth	MouthWidth	T Label	Row
8	7	14	23	21	13	1	1

8	9	15	23	21	13	12	12

Figure 6.8

goblets. Then perform a cluster analysis of the goblets. How does the dendrogram reflect the closeness of the goblets in the principal-component plot?

32

7 Non-hierarchical cluster analysis

Non-hierarchical cluster analysis aims to find a single grouping of a set of *n* objects by optimizing a criterion, for example by maximizing the between-group sum of squares. Other criteria in Genstat include maximizing the total between-groups Mahalanobis distance, minimizing the within-class dispersion or a criterion known as *maximal predictive classification*, which is designed specifically for binary data. For full definitions, see the *Guide to the Genstat Command Language*, Part 2 Section 6.20. This form of clustering includes the technique known as *K-means clustering*, where the criterion is usually the within-class dispersion.

To illustrate the menus we shall use some measurements taken on 30 bronze brooches (Doran & Hodson, 1975, *Mathematics and Computers in Archaeology*, Edinburgh University Press, Table 9.1). These are stored in Genstat spreadsheet Brooch.gsh (Figure 7.1).

Row	T Label	Foot length	Bow height	Coil diameter	Element diameter	Bow width	Bow thickness	Length
1	389	93	24	16	13	3.5	3.5	114
2	615	21	7	6	2	3.5	1.7	35
3	125	33	15	7	8	3.9	3.2	60
4	812	23	26	9	12	6.2	7.7	74
5	798	20	23	7	8	7.7	5.2	68
6	673	27	15	7	3	3.7	3.5	55
7	Thames	10	16	9	7	6.1	4.1	45
8	643	15	18	10	5	3.5	3.5	40
9	391	31	13	7	5	17.6	1.4	54
10	398	19	17	6	6	9.2	6.6	39

Before doing the cluster analysis, to counteract skewness in the variables, we transform each column of measurements x to log10(x+1). This can be done using the Calculate menu in the usual way. Alternatively, to save time, the transformed data are available in spreadsheet Logbrooch.gsh.

To obtain the Non-hierarchical Cluster Analysis menu you click on the Nonhierarchical line in the Cluster Analysis subsection in the Multivariate Analysis section of the Stats menu on the menu bar.

Figure 7.2 shows the menu set to use all the measurements to form four groups using the between-group sum of squares criterion.

Figure 7.2

7 Non-hierarchical cluster analysis

The Non-hierarchical Cluster Analysis Options menu (Figure 7.3) controls the way in which the search for the best grouping is carried out, and the output that is produced.

In Figure 7.3, we have asked Genstat to form the initial classification by finding the four objects that are furthest apart in the 7dimensional space defined by the measurements, using these objects as the "cores" of the initial groups, and allocating the other objects to the group with the nearest core. (Note: this is feasible only if the number of groups does not exceed the number of variates.) The Between-group interchanges box controls how Genstat generates new groupings from the initial classification. Here we are

Non-hierarchical Clu	ster Analysis Options	×						
Display								
Criterion value	Criterion value							
Classified data	Optimum classification							
Display values from	i initial classification							
Initial classification								
O Equal-sized groups	, by unit order							
Automatic, by dista	nce							
Between-group Intercl	nanges							
Transfer and swap								
O Swap only (fixed gr	oup sizes)							
O Fix at initial classific	ation							
× ?	OK Cancel	Defaults						
	UK Cancel	Defaults						

allowing objects both to be swapped between groups, and to be transferred from group to group. The setting Swap only would constrain the group sizes to remain the same throughout the search (which might be useful, for example, if you wanted groups of equal sizes, and chosen the Equal-sized groups, by unit order option for the Initial classification), and the setting Fix at initial configuration makes no changes.

You can arrange to store the final classification by using the Non-hierarchical Cluster Analysis Store Options menu (Figure 7.4), which is obtained by clicking on the Store button in the Non-hierarchical Cluster Analysis menu (Figure 7.2). To save the a factor defining the groups, you check the Grouping box, and type the name of a factor into the In box.

The output gives details of the initial classification and of the final (optimal) classification, showing the criterion value, how the objects are allocated to the groups and the mean values of the measurements in each group. In this example, the initial classification has been very successful. The optimum classification differs only in that the eighth object has been transferred from group 3 to group 4, and the 29th object from group 4 to group 3.

7.1 **Practical**

file Genstat spreadsheet Goblet.gsh (Figure 7.5) contains data on 25 goblets from prehistoric sites in Thailand (see page 147 of Manly, 1986, Multivariate Statistical Methods a Primer, Chapman & Hall, London). Perform a nonhierarchical classification into five groups. How does this

compare with the dendrogram produced in Practical 6.1?

8 Multivariate analysis of variance

Multivariate analysis of variance can be viewed as the extension of ordinary analysis of variance (as in Chapter 6) to handle several response variates at once. So, for example, instead of making assumptions of Normality for the residuals from a single response variate, we are now assuming multivariate Normality of residuals from several response variates.

We illustrate the analysis using data from an experiment to investigate sex and temperature effects on the growth of tumours in rats (see page 143 of Chatfield & Collins, 1986. Introduction to Multivariate Analysis, Chapman and Hall, London). Three rats of each sex were reared in each of three temperatures (4, 20 and 34). There was no blocking (i.e. this is a completely randomized

		Spreadsne	et [Tumour.gsh]		
Row	Sex Sex	! Temperature	TumourWeight	FinalWeight	InitialWeight
1	Male	4	0.24	16.51	18.15
2	Male	4	0.32	19.5	<mark>18.6</mark> 8
3	Male	4	0.2	19.84	19.54
4	Female	4	0.16	19.49	19.15
5	Female	4	0.17	19.81	18.35
6	Female	4	0.22	19.44	20.68
7	Male	20	0.33	23.3	21.27
8	Male	20	0.45	22.3	19.57
9	Male	20	0.35	18.95	20.15
10	Female	20	0.25	22	18.87

design). The weights of the rats were measured (prior to sub-cutaneous seeding of the tumours). The response variates, taken at the end of the experiment, are the tumour weight and the final weight (excluding the tumour). The data are available in spreadsheet

Tumour.gsh (Figure 8.28).

The MANOVA menu (Figure 8.2) is obtained by clicking on the MANOVA line in the Multivariate Analysis section of the Stats menu on the menu bar.

In Figure 8.2, we have specified a treatment structure of Sex*Temperature, to fit the main effects of sex and temperature, and their interaction (see Section 6.6). There is no block structure but we want to treat the variate InitialWeight as a covariate

Available data:		Data:	
Sex Temperature	->	FinalWeight TumourWeight	^
Operators:	Treatment structure	: Sex * Temperature	v
+	A Block structure:		
• /	Block structure:	InitialWeight	
•	Block structure:]

(so we check the Covariates box, and enter its name into the adjacent field). Covariates are included in the treatment model like variates in a linear regression. So, Genstat estimates a regression coefficient for them, and adjusts the other estimates and sums of squares to take account of their presence in the model (see *Guide to the Genstat Command Language*, Part 2 Section 4.3).

The MANOVA Options menu, shown in Figure 8.30, allows you to control the output from the multivariate analysis, and also to display output from the univariate anova's of the individual response variates. Here we have asked just to print the various tests from the multivariate analysis, and omitted the sums and squares and products of the treatment effects and residuals (which are involved in calculating the tests).

The output, shown below, indicates that there are sex and temperature effects, but no interaction and no effect of the covariate.

Term	d.f.	Pillai-Bartlett	Roy's	s maximum	Lawl	ey-Hotelling
		trace		root test		trace
Sex	1	0.6515		0.6515		1.8697
Temperature	2	0.8477		0.4949		1.5249
Sex.Temperature	2	0.2278		0.1605		0.2634
Covariate	1	0.1781		0.1781		0.2167

The analysis uses the MANOVA procedure (see *Guide to the Genstat Command Language*, Part 2 Section 6.6.1). This uses the ANOVA directive, which requires the design to be balanced (see Section 6.7 or *Guide to the Genstat Command Language*, Part 2 Section 4.7). For unbalanced data, you can use the RMULTIVARIATE procedure, but this is not currently accessible through the menus.

8.1 Practical

Genstat spreadsheet file Skull.gsh (Figure 8.4) contains data on 150 male Egyptian skulls from five different epochs (see Practical 3.1 and pages 4 and 5 of Manly, 1986, *Multivariate Statistical Methods a Primer*, Chapman & Hall, London). Perform a multivariate analysis of variance. Are there any epoch differences?

Figure 8.4

9 Classification trees

A classification tree is a device for predicting (or identifying) the class to which an unidentified object belongs. The starting point is a sample of objects from the various classes. Measurement recorded on the sample may be either continuous (supplied in variates) or discrete (supplied in factors). Below we shall illustrate the methods using the iris data from Chapter 3, where the data were all continuous (see Figure 3.1).

The Classification Tree menu (Figure 9.1) is in the Trees sub-option of the Multivariate Analysis option of the Stats menu on the menu bar.

In Figure 9.1, we have specified Species as the name of the factor defining the groups to be predicted, and entered the names of all the measurements into the X-variates box. The Save Tree in box allows you to specify a name for the *tree* structure that Genstat will generate to represent the classification tree. If you do not do this, Genstat will use its own private name, but you will not find it easy to use the tree outside the menus. Here we have specified the name IrisTree.

The tree progressively splits the objects into subsets based on their the measurements. values for Construction starts at a node known as the *root*, which contains all of the objects. A factor or variate is chosen to use there that "best" splits the individuals into two subsets. For example, in the tree for the irises, the first division is done by seeing whether the petal lengths are less than or greater then 2.450 (see the output below). The tree is then extended to contain two new nodes, one for each of the subsets, and factors or variates are selected for use at

each of these nodes to subdivide the subsets further. The process stops when either no factor or variate provides any additional information, or the subset contains individuals all from the same group, or the subset contains fewer individuals than a limit specified by the Number of items to stop splitting field of the Classification Tree Options menu (Figure 9.2). The nodes where the construction ends are known as *terminal nodes*.

Factors may have either ordered or unordered levels, according to whether or not the X-Variable factor levels ordered box is checked. For example, a factor called Temperature with levels 5, 10 and 20 would usually be treated as having ordered levels, whereas levels labelled 'London', 'Moscow', 'New York', 'Ottawa' and 'Paris' of a factor

9 Classification trees

called T_{OWN} would be regarded as unordered. For unordered factors, all possible ways of dividing the levels into two sets are tried. With variates or ordered factors with more than 2 levels, a suitable value p is found to partition the individuals into those with values less than or greater than p. The radio buttons in the Method and Anti-end-cut-factor boxes in the Classification Tree Options menu allow you to choose how to assess the potential splits: whether to use Gini information or mean posterior improvement, and whether to use adaptive anti-end-cut factors. Details are given in the *Guide to the Genstat Command Language*, Part 2 Section 6.21.1.

The Display box of the Classification Tree Options menu (Figure 9.2) is set to print the tree only in "indented" format. This is a representation analogous to those used to display botanical trees. In the iris output, printed below, the first variable to examine is Petal_Length. If this is less than 2.450, the iris specimen is identified as *Setosa*. Otherwise you progress to index 2, and examine Petal_Width. So, a specimen of *Versicolor* might be identified by the sequence: (1) Petal_Length > 2.450; (2) Petal_Width < 1.750; (3) Petal_Length > 4.950; (5) Petal_Width > 1.550 *Versicolor*. Notice that the same variable can be used several times as the observed characteristics are refined on the way to an identification.

1 Petal_Length<2.450 Setosa 1 Petal_Length>2.450 2 2 Petal_Width<1.750 3 3 Petal_Length<4.950 4 4 Petal_Width<1.650 Versicolor 4 Petal_Width>1.650 Virginica 3 Petal_Length>4.950 5 5 Petal_Width<1.550 Virginica 5 Petal_Width>1.550 Versicolor 2 Petal_Width>1.750 6 6 Petal_Length<4.850 Virginica 6 Petal_Length>4.850 Virginica

Generally the construction of a classification tree will result in *over-fitting*. That is, it will form a tree that keeps selecting factors or variates to subdivide the individuals beyond the point that can be justified statistically. The solution is to prune the tree to remove the uninformative sub-branches. The pruning uses *accuracy* figures, which are stored for each node of the tree. The tree also stores a *prediction* for each node, which corresponds to the group with most individuals at the node. For each node of a classification tree, the accuracy is the number of misclassified individuals at the node, divided by the total number of individuals in the data set. It thus measures the "impurity" of the subset at that node (how far it is from it from being homogeneous i.e. having individuals all from a single group).

You can prune the tree using the Tree Pruning menu (Figure 9.3), which is accessible from Tree subsection in the Multivariate Analysis section of the menu bar or by clicking on the Prune button on the Classification Tree menu. As we have loaded the menu from the Classification Tree menu, Genstat has filled in the name of the tree automatically.

In the Display box, we have asked for the relationship between the impurity and the number of terminal nodes to be presented in a graph (Figure 9.4) and a table (below).

The table and graph show that the impurity of the pruned trees drops rapidly as the number of terminal nodes increases from one up to three, but then tails off more slowly. This suggests that we should prune down to three terminal nodes, but no further. This tree is the fifth in the sequence of pruned trees (count from the right of the graph, or notice the numbering in first column of the table).

Figure 9.3

The initial summary, generated by the Summary check box, lists the number of nodes (5) and terminal nodes (3) in the tree, its misclassification rate and which variables it uses. The details section (from the Details check box) gives information about each node, referring to the numbering displayed in the tree diagram at the end of the output (which is generated by the Numbered Diagram check box).

Note, if possible, it is best to use "accuracy" figures that are derived from a different set or sets of data from that which was used to construct the tree. This cannot be done through the menus, but you can use the BCVALUES procedure, which is described in the *Guide to the Genstat Command Language*, Part 2 Section 6.21.3.

Another useful procedure, which also cannot be accessed currently through the menus is BCIDENTIFY. This has a convenient interactive interface, that asks you to enter the information required by the tree as and when it is needed. (For details of the options and parameters that allow you to use it in batch mode, see the *Guide to the Genstat Command Language*, Part 2 Section 6.21.3). To run the procedure in this way, you merely need to set the TREE option to the name of the tree, here IrisTree. If we type the command

BCIDENTIFY [TREE=IrisTree]

and execute it, for example by clicking on the Submit Line line in the Run menu on the menu bar, Genstat asks the question in Figure 9.7. (Our answer is yes.)

Do you want to print a tra	nscript of the identification?

Figure 9.7

9 Classification trees

The next question is in Figure 9.8, to which we shall answer that the petal length is greater than 2.450. (Check the box and click on OK.)

Please	select the appropriate cha	racteristic:	
	Petal_Length<2.450	C exit	
	Petal_Length>2.450		

This generates the question in Figure 9.9, to which we shall answer that the petal width is less than 1.750.

Please select the appropriate cha	
Petal_Width<1.750	Cexit
C Petal_Width>1.750	

We have now reached the terminal node, and Genstat asks if we want to print the identification (Figure 9.10). It would be best to take the default suggestion, of yes, here as we have not set the option of BCIDENTIFY that would save the information! The output shows first a

Do you want to print the id	lentification?	
C no	ves	

transcript of the questions and answers (as requested in Figure 9.7), and then the identification of *Versicolor*.

Identification using a classification tree

Observations: Petal_Length>2.450 Petal_Width<1.750

Identification: Versicolor

9.1 Practical

Genstat spreadsheet file Skull.gsh (Figure 9.11) contains data on 150 male Egyptian skulls from five different epochs (see Practical 3.1 and pages 4 and 5 of Manly, 1986, *Multivariate Statistical Methods a Primer*, Chapman & Hall, London).

Form a classification tree. Prune down to 20 terminal nodes. What is the misclassification probability?

Figure 9.11

10 Regression trees

Regression trees are very similar to classification trees, except that the attribute to predict is the value of a response variate rather than the level of a group factor. So the starting point is now a sample of observations with various values of the response. As in a classification tree, the measurements recorded on the sample may be either continuous (supplied in variates) or discrete (supplied in factors). Below we shall illustrate the methods using the pollution data from Chapters 1 and 2, where the data were all continuous (see Figure 1.1).

The Regression Tree menu (Figure 10.1) is a sub-option of the Regression Analysis option of the Stats menu on the menu bar. In Figure 10.1, we have specified SO2 as the response variate, and entered the names of all the measurements into the X-variates box. The Save Tree in box allows you to specify a name for the *tree* structure that Genstat will generate to represent the classification tree. If you do not do this, Genstat will use its own private name, but you will not find it easy to use the

tree outside the menus. Here we have specified the name RegTree.

The tree progressively splits the observations into subsets based on their values for the measurements. Construction starts at a node known as the *root*, which contains all of the observations. A factor or variate is chosen to use there that "best" splits the observations into two subsets. The aim is to form subsets that have similar values for the response variate. The predicted value of the response variable

at each node of the tree is the mean of its value for the subset of observations at that node. The *accuracy* of the node is the squared distance of the values of the response variate from their mean for the observations at the node, divided by the total number of observations. The potential splits at the node are assessed by their effect on the accuracy, that is the difference between the accuracy of the node and the sum of the accuracies of the two potential successor nodes. The node will become a terminal node if none of the splits provides any improvement in accuracy, or if the mean square of the observations at the node is less than a limit that can be specified in the Regression Tree Options menu (Figure 10.2). As in a classification tree, factors may have either ordered or unordered levels, according to whether or not the X-Variable factor levels ordered box is checked (see Chapter 9 for more details).

The menu also allows you to select the output to display. Here we have asked for the

tree in "indented" format (as we did earlier for the classification tree in Chapter 9). So, in the output below, the first variable to examine is Manuf. If this is less than 748.0, you progress to index 2, and examine Pop. Otherwise, you find the other line for index 1, further down the tree, which tells you to go to index 33 and form another split involving Manuf. The terminal nodes (at which predictions of SO2 are made) are identified by the fact that they are followed by real numbers (with decimal points) rather than integers. So, for example, at index 5, SO2 is predicted to be 13.

As with classification trees (Chapter 9), the construction of a regression tree will generally result in *over-fitting*. That is, it will form a tree that keeps selecting factors or variates to subdivide the individuals beyond the point that can be justified statistically. The solution is again to prune the tree to remove the uninformative sub-branches. The pruning uses *accuracy* of the nodes of the tree, as defined above.

You can prune the tree using the Tree Pruning menu (Figure 10.3), which can be opened from Tree subsection in the Multivariate Analysis section of the menu bar or by clicking on the Prune button on the Regression Tree menu. As we have loaded the menu from the Regression Tree menu, Genstat has filled in the name of the tree automatically.

Figure 10.3

In the Display box, we have asked for the relationship between the accuracy and the number of terminal nodes to be presented in a graph (Figure 10.4) and a table (below). The table and graph show that the impurity of the pruned trees drops rapidly as the number of terminal nodes increases from one up to about ten, but then tails off more slowly. This suggests that we should prune down to ten terminal nodes, but no further. This tree is the 26th in the sequence of pruned trees.

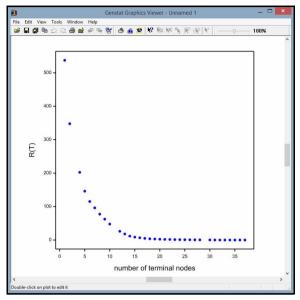

Figure 10.4

You can get the number of the tree from the index in the first column of the table, or by counting from the right of the graph, or by using the Data-info tool on the graph, as shown in Figure 10.5. To select the tool, you click on the icon with the arrow and question mark at the left-hand end of the Graphics Toolbar. The viewer will then display details of a point when you rest the pointer nearby.

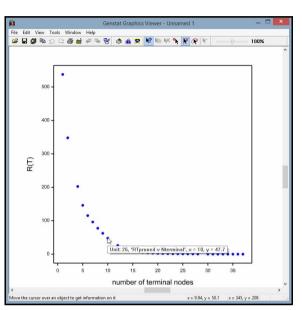

Figure 10.5

By clicking the button Replace with pruned we can replace contents of the tree RegTree with this smaller tree. We simply need to fill in the number of the tree (26) in the resulting menu (Figure 10.6), click on OK, and then cancel the Tree Pruning menu.

Figure 10.6

The pruned tree can be displayed using the Regression Tree Further Output menu (Figure 10.7), obtained by clicking on the Further Output button on the Regression Tree menu. Here we have asked to print the tree in indented form again, to print a summary of its properties and to display it in a graph (see Figure 10.8).

1 Manuf<748.0 2 2 Pop<190.0 3 3 Wind<9.800 4 4 Temp<-50.05 27. 4 Temp>-50.05 51. 3 Wind>9.800 94. 2 Pop>190.0 5 5 Days<108.0 12. 5 Days>108.0 6 6 Temp<-59.35 15. 6 Temp>-59.35 7 7 Wind<11.20 32.64 7 Wind>11.20 13.50 1 Manuf>748.0 8 8 Manuf<2518 9 9 Precip<32.98 35. 9 Precip>32.98 63.33 8 Manuf>2518 110.

The initial summary, generated by the Summary check box, lists the number of nodes (19) and terminal nodes (10) in the tree, its residual sum of squares, degrees of freedom and mean square, and the variables that it uses. Note, if possible, it is best to use "accuracy" figures that are derived from a different set or sets of data from that which was used to construct the tree. This cannot be done through the menus, but you can use the BCVALUES procedure, which is described in the *Guide to the Genstat Command Language*, Part 2 Section 6.21.3.

10 Regression trees

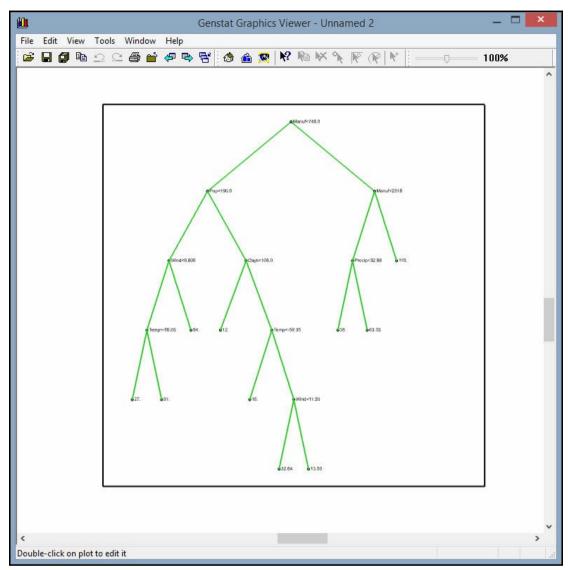

Figure 10.8

10.1 Practical

Genstat spreadsheet file Water.gsh (Figure 10.9) contains data about the water usage of a production plant (last column of the sheet). There are also four variates that may be associated with the amount of water that has been used: the average temperature, the amount of production, the number of operating days and the number of employees. (See page 352 of *Applied Regression Analysis* by Draper & Smith, 1981, Wiley, New York.)

Form a regression tree to predict water usage from the other variates.

Row	Employ	Opdays	Product	Temp	Water

11 Generalized Procrustes analysis

Generalized Procrustes analysis allows you to produce a consensus configuration of points from several input configurations. It is often used in sensory analysis, for example of food or wine, where the input configurations will be assessments made of various attributes of the food or wine samples.

Figure 11.1 shows an example data set from an evaluation of the appearance of port-wines by Williams & Langron (1984, *Journal of*

Figure 11.1

the Science of Food and Agriculture, **35**, 558-568), stored in spreadsheet file Port.gsh. There were six assessors (labelled A-F in column 1), eight samples of port (columns Sample1 - Sample8), and the attributes measured by each assessor are described in the Attribute column. Notice that this is an example of *free choice profiling*; the assessors were not required to observe the same attributes, but they could each define their own. The only constraint is that each assessor must be consistent in their definition of an attribute over the samples. Also, for the analysis to work, each assessor must observe the same number of attributes. However, it is valid to include a "null" attribute of zero observations for assessors that have observed too few (assessors D, E and F here).

The analysis treats the observations from each assessor as a configuration of n points (one for each sample) in p dimensions (one for each attribute), and forms a *centroid* configuration that gives a consensus view of how the assessors perceive the ports. The basic data for the analysis is a set of attribute \times sample matrices, containing the measurements made by each assessor.

These can be formed by first deleting the Attribute column (put the cursor into any cell in the column, then select the Current Column sub-option of the Delete option of the Spread menu, as shown in Figure 11.2.

4	A	1	1	2	0	0	0	0	e

Figure 11.4

The first of the six new spreadsheets is shown in Figure 11.4.

We need to delete the assessor column. We then convert the spreadsheet into a matrix by selecting the Convert sub-option of the Sheet option of the Spread menu to open the Convert Sheet menu. In that menu (Figure 11.5), we select Matrix as the Sheet Type, give it a name (here M1), and click on OK. We now need to transpose the spreadsheet, by selecting the Transpose sub-option of the Manipulate option of the Spread menu, and we can rename the transposed matrix (e.g. to X1) by using the Sheet Properties menu (opened by selecting the Properties suboption of the Sheet option of the Spread menu. We then need to repeat the process for the other new spreadsheets, giving each transposed matrix a different name (X2 - X6).

However, as spreadsheet manipulation is not the main point of this Chapter, the transposed matrices can be found in spreadsheet book Portmatrices.gwb, as shown in Figure 11.6. (The original data were presented in Figure 11.1 in order to display their structure more clearly.)

The Generalized Procrustes menu (Figure 11.7) is opened by selecting the Generalized Procrustes sub-option of the Multivariate Analysis option of the Stats menu. The main task is to set the Data to be analysed to the matrices containing the configurations (here $\times 1 - \times 6$).

The common centroid configuration is formed by the operations of translation to a common origin, rotation and reflection of axes, and possibly also scale changes. It is found iteratively, using either Gower's or Tenberge's method, by minimizing the sum of the

Figure 11.7

squared distances between the centroid and each individual configuration. To give a unique representation, the final centroid is defined using its principal axes.

The Generalized Procrustes Options menu (Figure 11.8) allows you to select the type of scaling to be done. *Isotropic* scaling, which scales the all the dimensions of each configuration by an equal amount, takes place during the Procrustes analysis. The alternative is to scale each configuration prior to the analysis so that the trace of each matrix is one. If this separate scaling is used, the subsequent residuals represent pure lack-of-fit and the scaling factors given in the results represent differences in relative size/spread of the original (centred) configurations, whereas for overall isotropic scaling the scaling factor contains components of both size and lack-of-fit.

The first graph (Figure 11.9) plots the positions of the eight port-wines in the consensus configuration; the default is to display the first three principal axes. This allows you to study the similarities of the port-wines, as observed overall by the assessors.

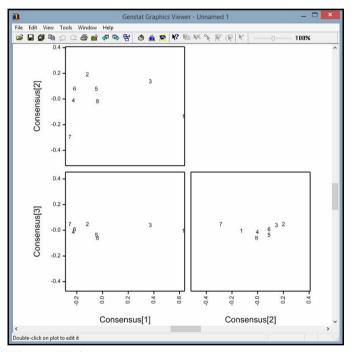

Figure 11.9

The individuals plot (Figure 11.10) is similar, but also shows how the points in each configuration are mapped to the equivalent points of the consensus. This allows you to assess the consistency of the assessors.

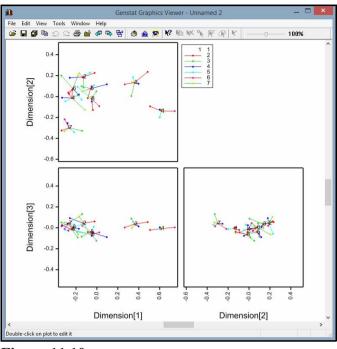

Figure 11.10

The projection plot (Figure 11.11) shows the fitted projections of the attributes, as observed by each assessor, onto the first two principal axes. A different colour is used for each attribute, taking the standard order of the Genstat pens (by default red, green, blue, cyan, mauve, yellow, brown etc.). Each line is numbered by its assessor. This shows how each of the attributes contributes to the consensus picture.

Notice that the fitted attributes (plotted in cyan) for the null attributes of assessors 4-6 are negligible. The scores fitted to these null attributes can be regarded as representing

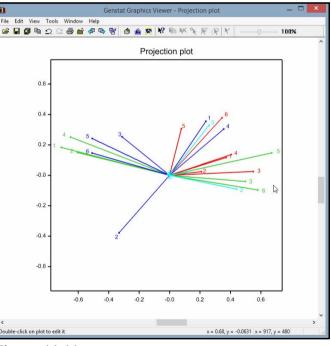

Figure 11.11

random variation, and used as a yardstick for assessing the other scores. (However, if one of the null fitted scores were found to be noticeable, this would indicate a large Procrustes deviation between this assessor and the consensus – which might suggest that this assessor should treated separately.)

11.1 Practical

Genstat spreadsheet file Bordeaux.gsh contains results of a sensory assessment of aroma attributes of 24 Bordeaux wines. Do a generalized Procrustes analysis and examine a consensus plot of the first two dimensions. (Hint: use the Ten Berge method to speed convergence.) Rows 1-5 are St Estèphe wines, 6-10 are St Julien, 11-15 are Margaux, 16-20 are St Emilion, and 21-24 are regional Bordeaux wines (see

the row labels of the matrices). Can you see this structure reflected in the plot?

12 Other facilities

This chapter illustrates menus from most of the main areas of multivariate analysis provided by Genstat. Other menus are listed below with references to sections in the *Guide to the Genstat Command Language* describing the associated commands and methodology:

Discriminant analysis Factor analysis Correspondence analysis Canonical correlation analysis Redundancy analysis Canonical correspondence analysis Partial least squares regression Multivariate analysis of distance Part 2 Section 6.5, Part 2 Section 6.11, Part 2 Section 6.13, Part 2 Section 6.9, Part 2 Section 6.14, Part 2 Section 6.15, Part 2 Section 6.8, and Part 2 Section 6.6, 3.

Other multivariate facilities, not available through the menus, include ridge and principalcomponent regression (procedure RIDGE; Part 2 Section 6.7), analysis of skew symmetry (procedure SKEWSYMMETRY; Part 2 Section 6.17), the construction of identification keys (procedure BKEY; Part 2 Section 6.22) and random classification forests (procedure BCFOREST).
